

# Lecture 1

- Reading CH4103, unit 4; Clayden Ch 6, 11.
- Reactions of carbonyl compounds.

← consider this part today.

- Reactions of the carbonyl group:

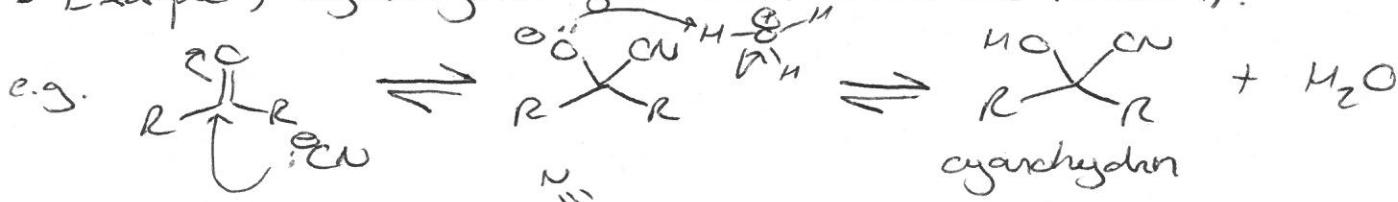

i) oxidation/reduction.

ii) acid/base reactions (the oxygen atom is basic)

iii) addition reactions (the carbon atom is electrophilic)

- The carbon atom can react with nucleophiles while the oxygen atom interacts with a Lewis or Brønsted acids.

- Example) Cyanoaceton formation (reversible reaction).

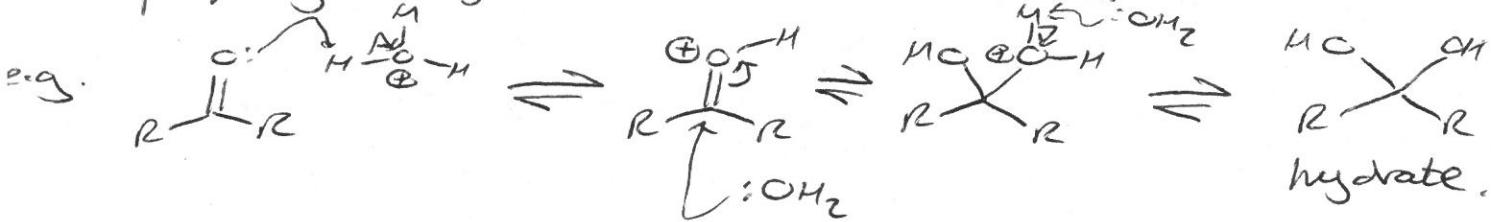

Bürgi-Dunitz angle of  
nucleophilic attack  
= 107°

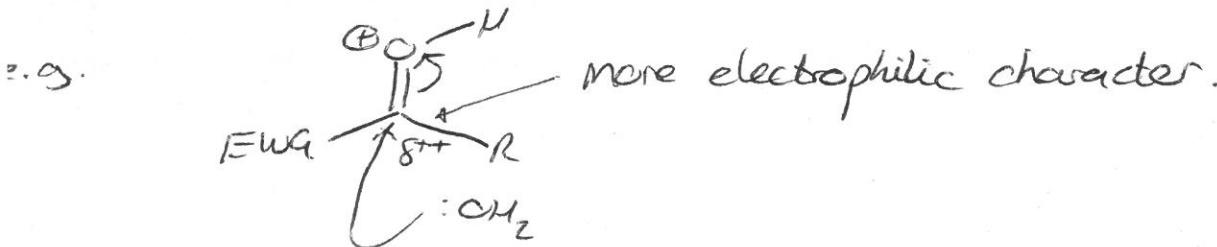

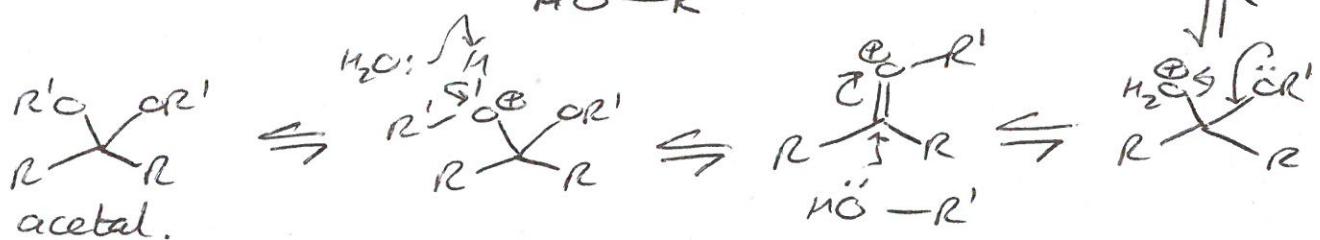

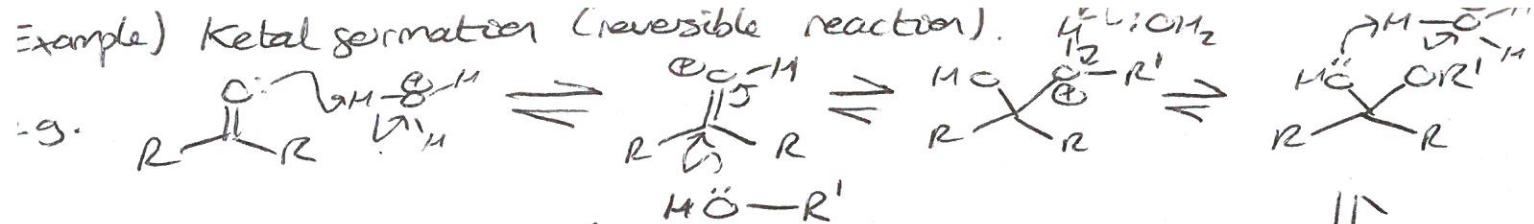

HOMO = filled C s orbital  
LOMO = empty π\* orbital

- Example) Hydrate formation (reversible reaction)

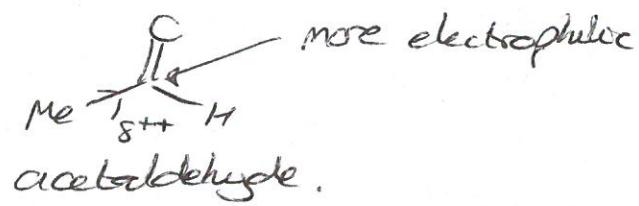

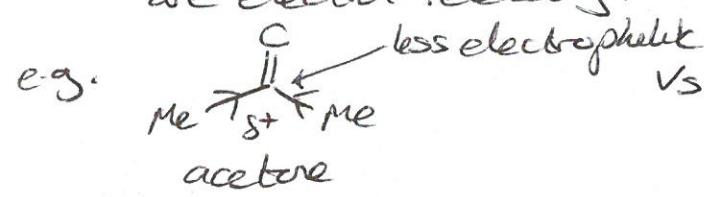

Note: EWG attached to the carbonyl carbon atom make addition more favorable

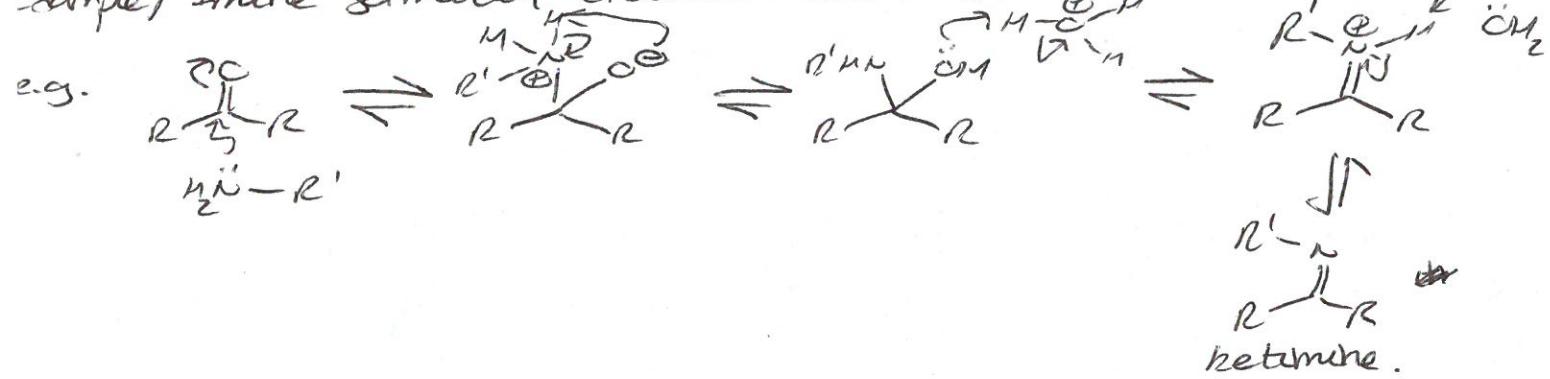

$\text{H}^+$  cat = TsOH or  $\text{H}_2\text{SO}_4$ .

Note: Ketones are less electrophilic than aldehydes as alkyl groups are electron-releasing.

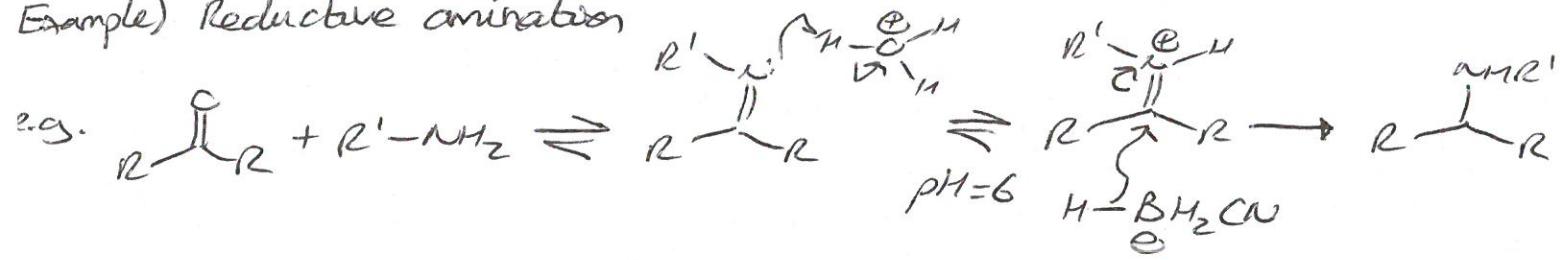

Note: Removal of  $\text{H}_2\text{O}$  favours acetal / ketal formation (Dean-Stark apparatus, molecular sieves,  $\text{MgSO}_4$  etc.).

Example) Imine formation (reversible reaction).

Example) Reductive amination

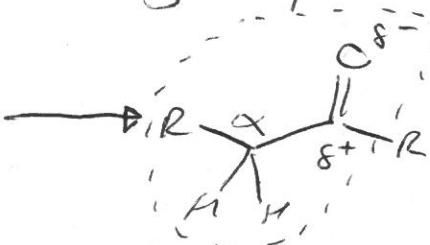

Note:  $\text{Na}(\text{CN})\text{BH}_3$  is a milder hydride donor compared to  $\text{NaBH}_4$  due to the CN EWG. This reagent is selective toward reduction of iminium ions and it prevents reduction of starting aldehydes or ketones.

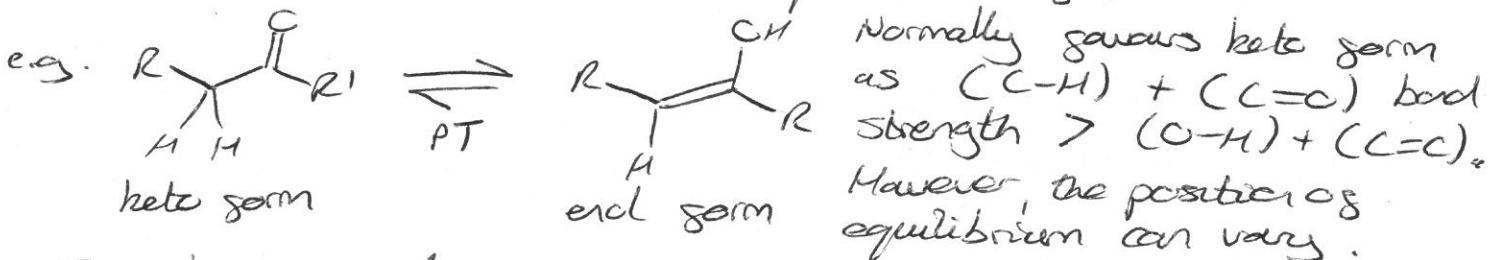

## Lecture 2

- Reading CH4103, unit 4; Clayden Ch 8, 20, 26.
- Reactions of carbonyl compounds.

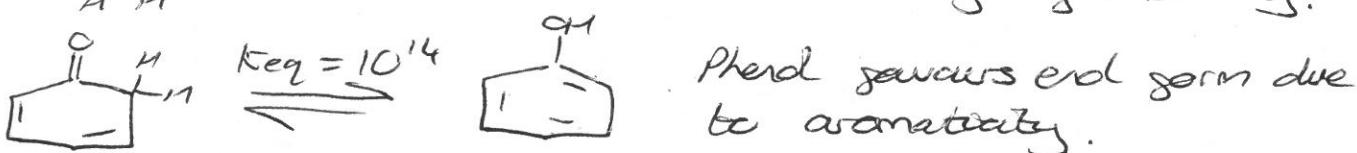

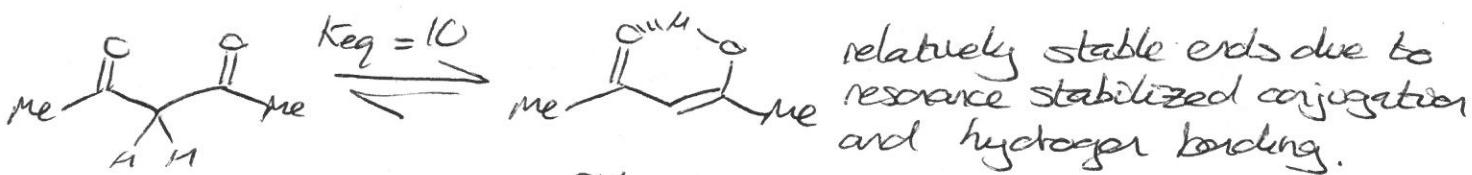

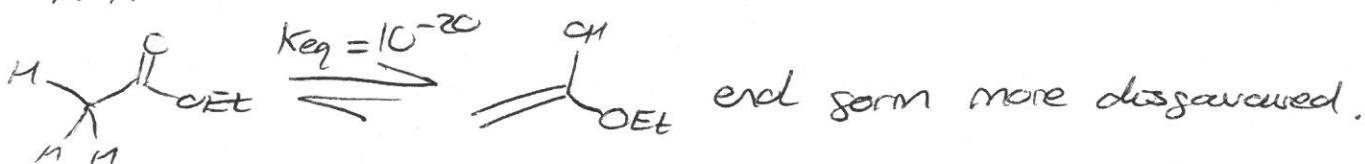

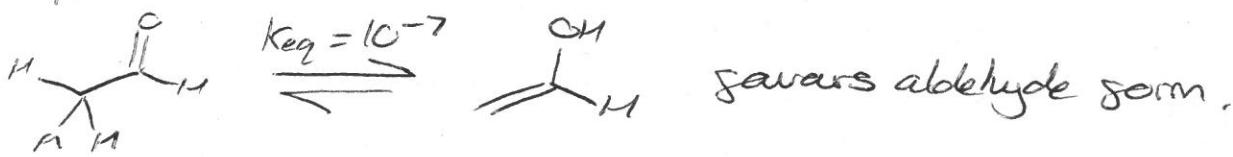

consider this part next

- Enol tautomers (intramolecular proton transfer)

- Examples of enols.

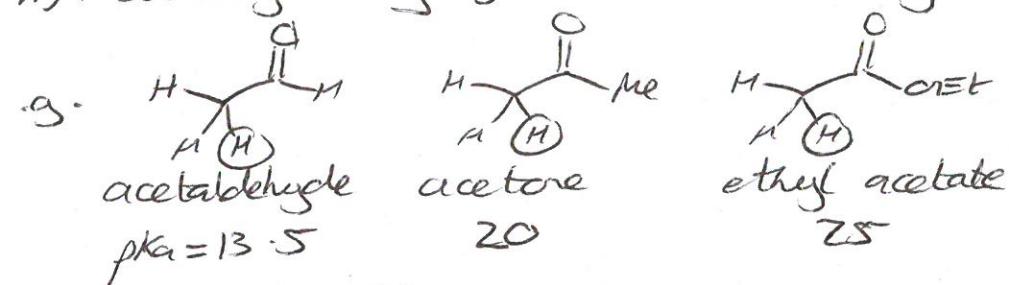

- The hydrogen atoms attached to the  $\alpha$ -carbon of a carbonyl compound are weakly acidic as deprotonation gives rise to an anion stabilized through delocalization over the  $\pi$  system, and is ultimately placed on an electronegative oxygen atom.

Note: Reactions which are dominated by charges and electrostatic interactions (hard) occur at oxygen, whereas reactions that are dominated by orbital interactions (soft) occur at the  $\alpha$ -carbon.

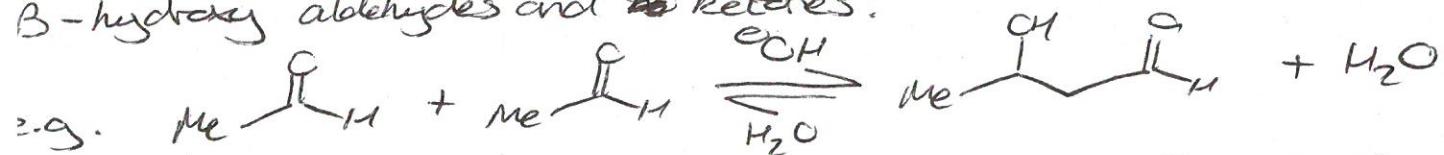

The pKa of the  $\text{C}(\text{O})-\text{H}$  depends on:

- i) The functional group that the  $\text{C}=\text{O}$  is part of
- ii) The resonance properties of the substituent
- iii) Electronegativity of the atoms directly connected to the  $\text{C}=\text{O}$

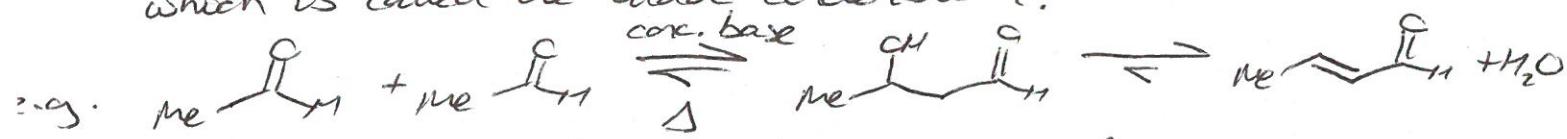

### The aldol addition reaction.

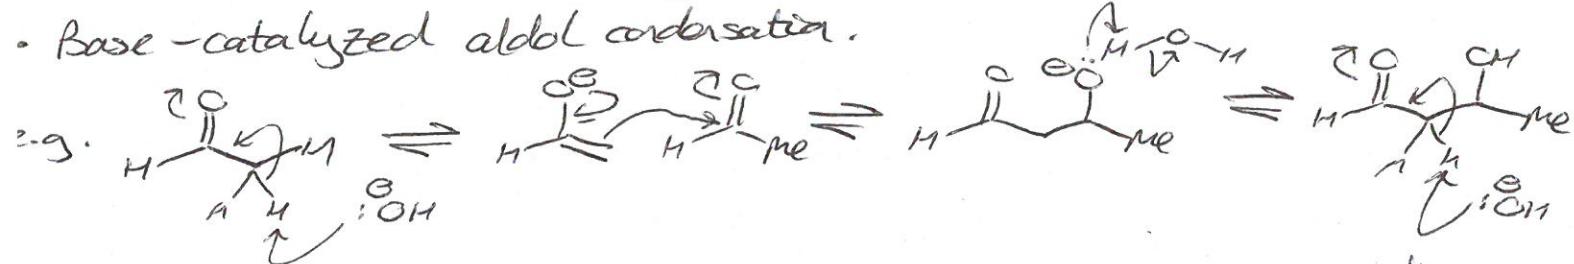

Aldehydes and ketones undergo the aldol addition reaction to form  $\beta$ -hydroxy aldehydes and ~~ketones~~ ketones:

Note: Using more forcing conditions (stronger acid/base, heat), dehydration occurs to give  $\alpha,\beta$ -unsaturated carbonyl compounds, which is called the aldol condensation.

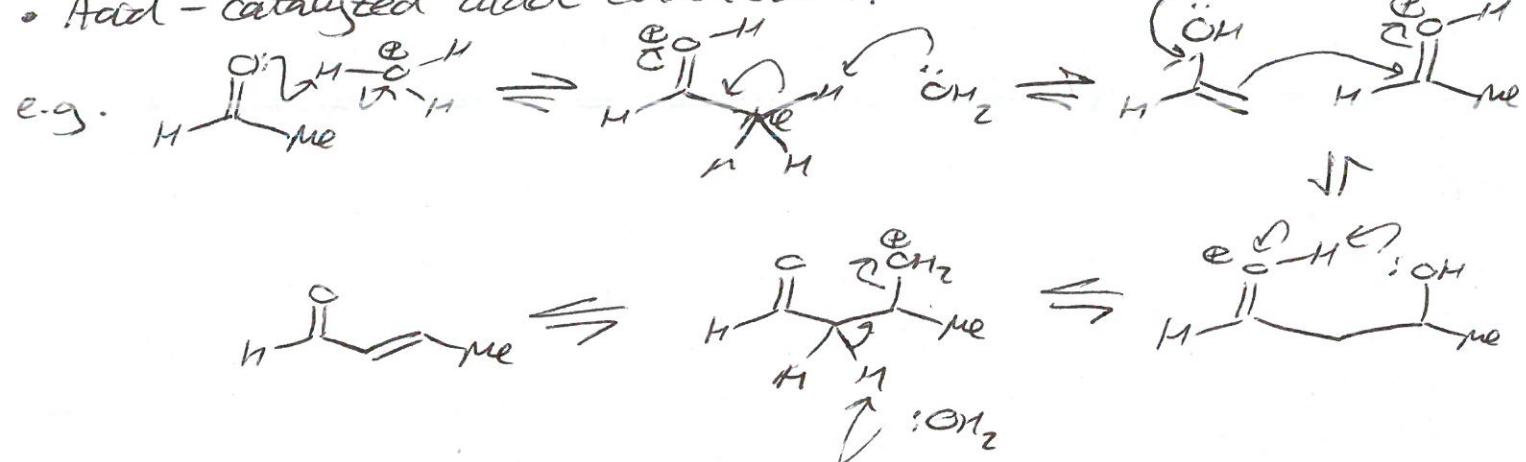

### Base-catalyzed aldol condensation.

Concentrated base or heat is needed  
as  $\text{^-OH}$  is a poor LG  
(E1cb elimination)

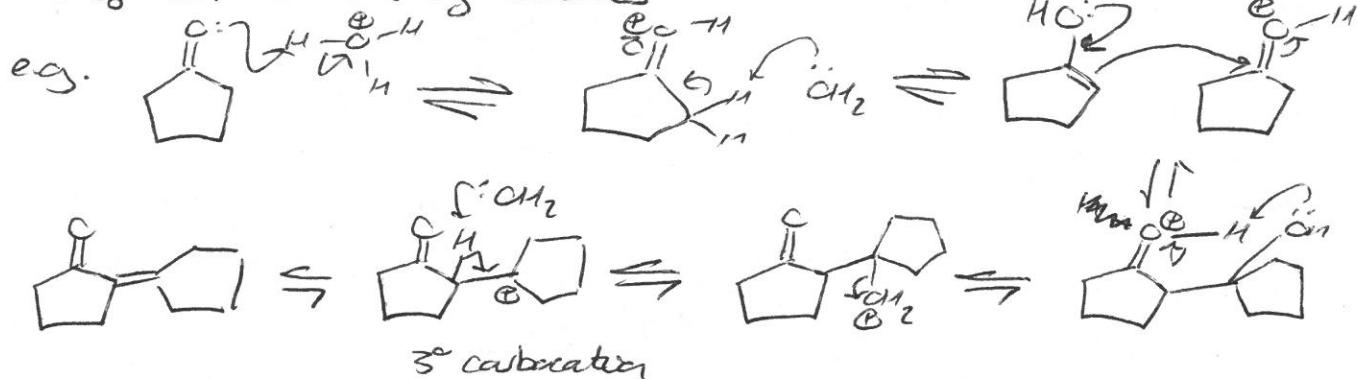

### Acid-catalyzed aldol condensation.

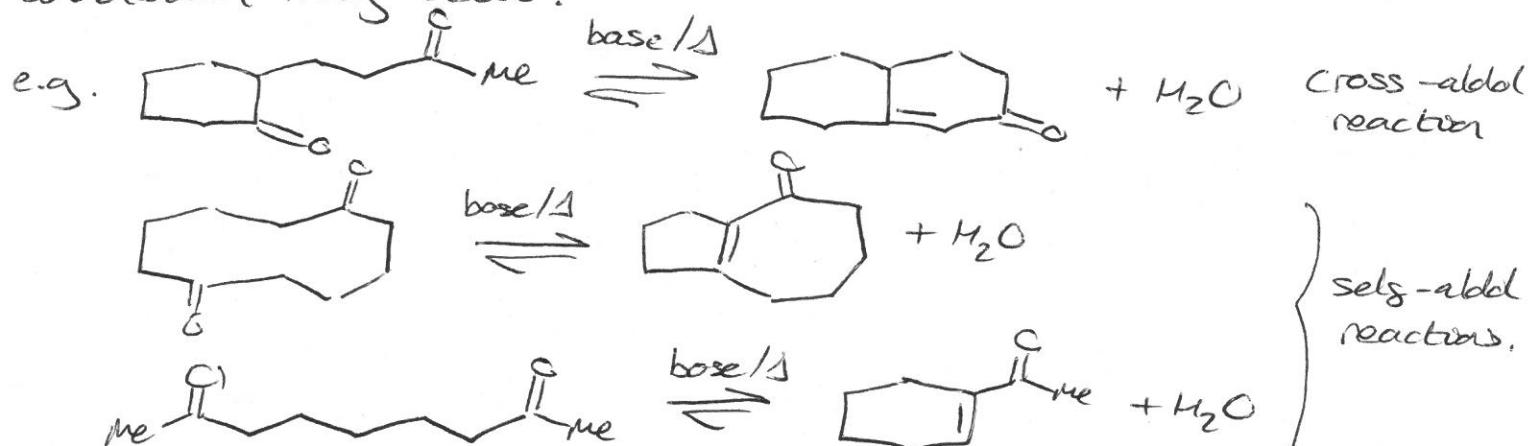

### Lecture 3

- Reading Clayden Ch 26.
- Self-condensation of ketones

- Intramolecular ~~self~~ aldol condensation.

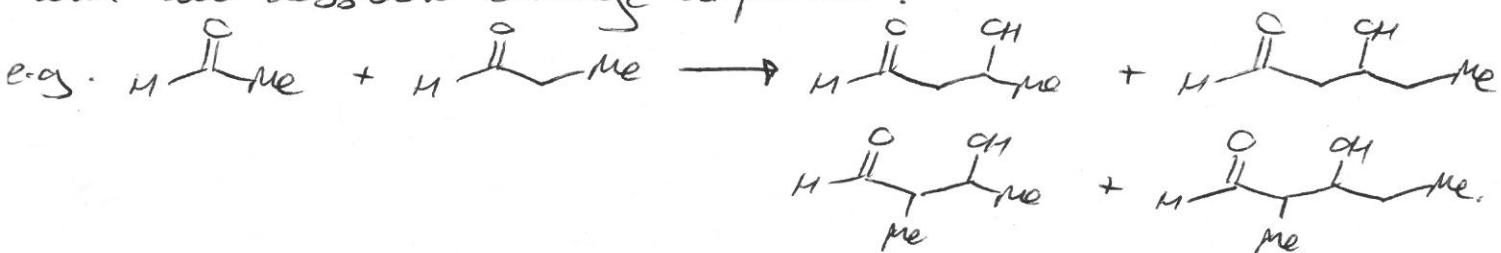

If a molecule has 2 carbonyl functions, an intramolecular aldol condensation may occur.

Note: Reversibility of all steps in the aldol condensation means that the most stable product is formed  $\Rightarrow$  five or six-membered rings typically favoured.

- Crossed-aldol reactions.

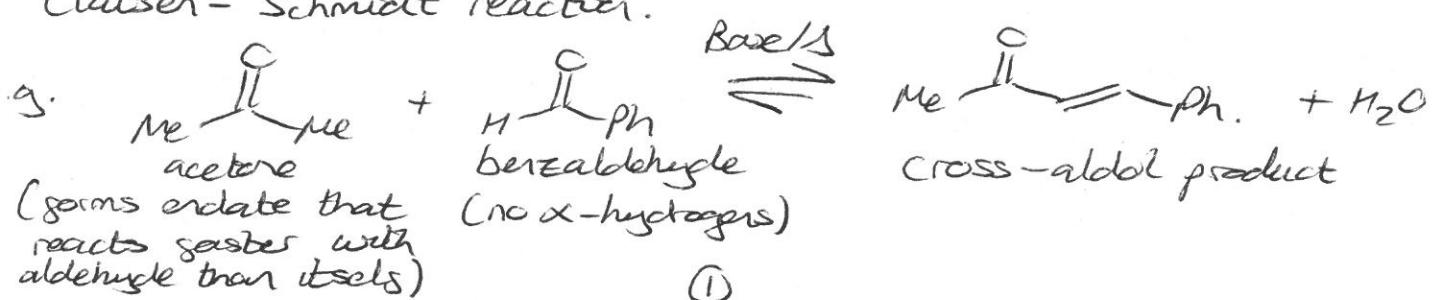

What happens if an aldol condensation/addition reaction is carried out with two different carbonyl compounds?

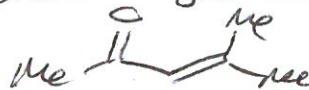

4 different aldol addition products

- If only one of the two carbonyl compounds has  $\alpha$ -hydrogens (enolizable), only one can form the enolate ion.

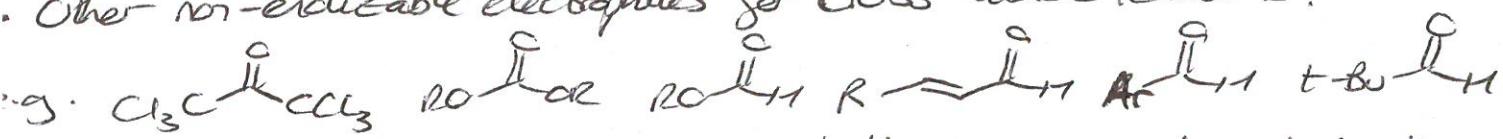

Claisen-Schmidt reaction.

Aldehydes are more electrophilic than ketones and all steps in the mechanism are reversible and the product formed is more thermodynamically stable than

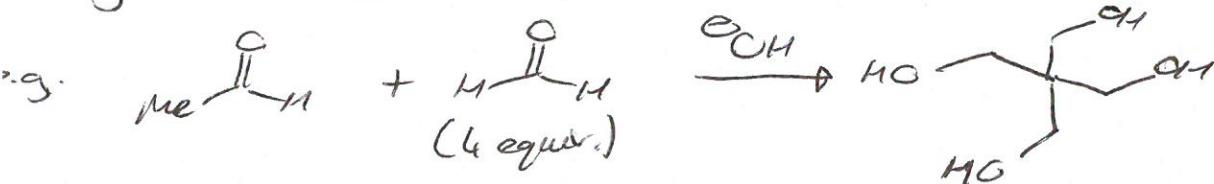

- Other non-enolizable electrophiles for cross-aldol reactions.

Note: None have  $\alpha$ -hydrogens. Also bulky groups adjacent to the  $\text{C}=\text{O}$  bond slow down the addition reaction.

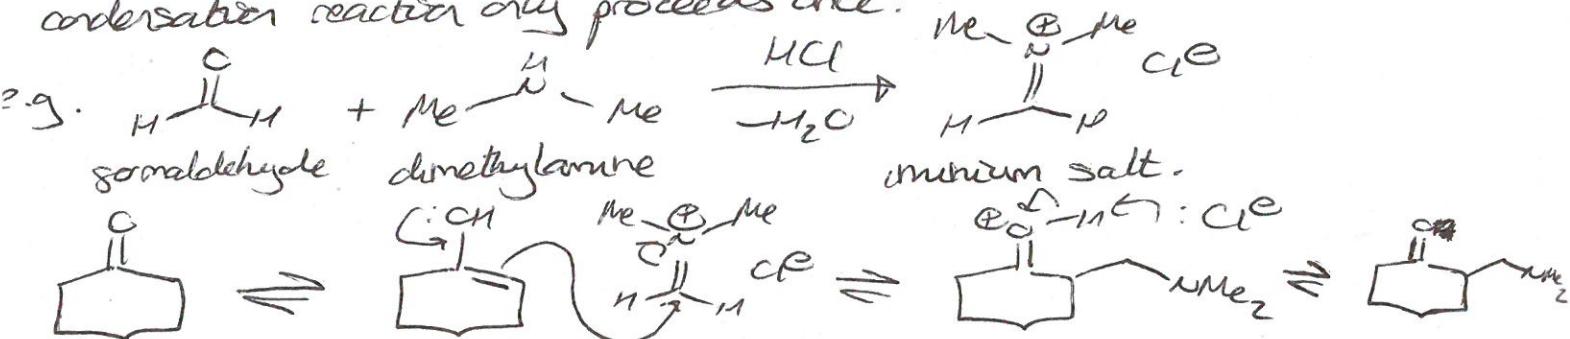

- Why not use formaldehyde as non-enolizable acceptor?

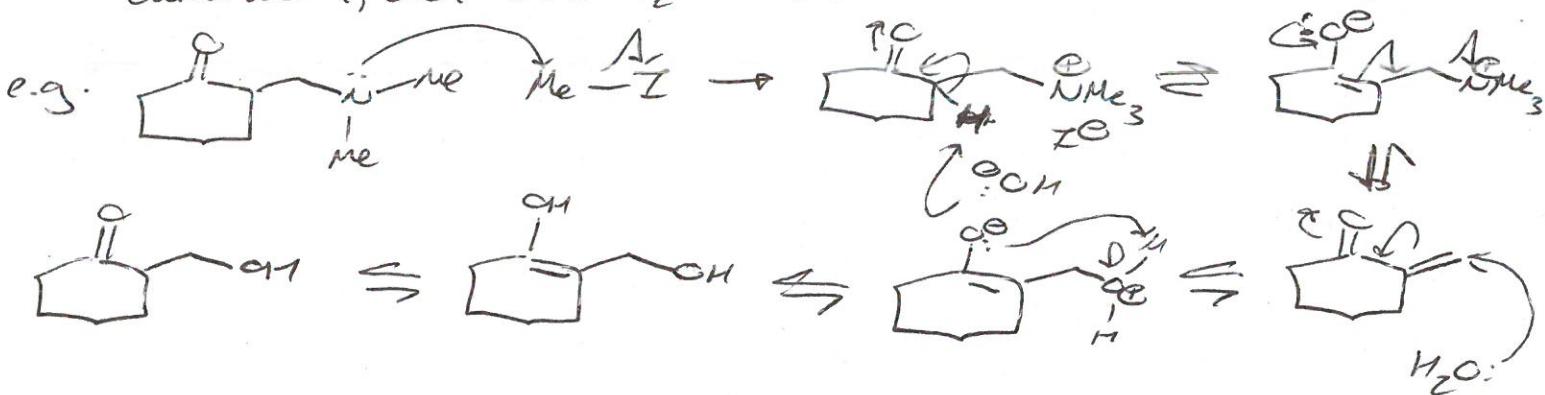

Note: Formaldehyde is very reactive and the aldol reaction proceeds until all enolizable  $\alpha$ -hydrogens have been substituted. A general Cannizzaro reaction (hydride transfer to the  $\text{C}=\text{O}$ ) gives the final product.

- The Mannich reaction.

Generates a less reactive formaldehyde analogue so that condensation reaction only proceeds once:

Note: To get the  $\beta$ -hydroxyketone, activate amine to be a good LG, elimination, then add  $\text{H}_2\text{O}$  via Michael addition (Unit 2)

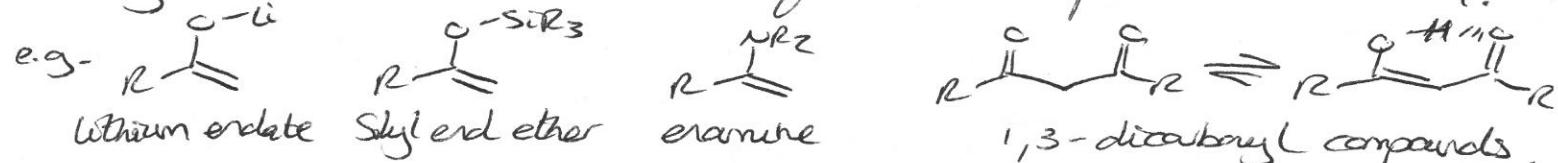

## Lecture 4

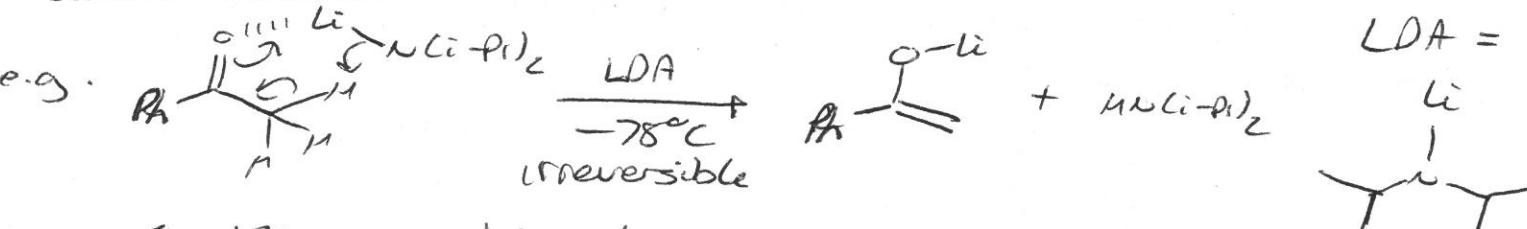

- Reading Clayden Ch 26.

- End equivalents.

It is difficult to control the reactivity and regioselectivity of many ends and endates. End equivalents can provide a solution.

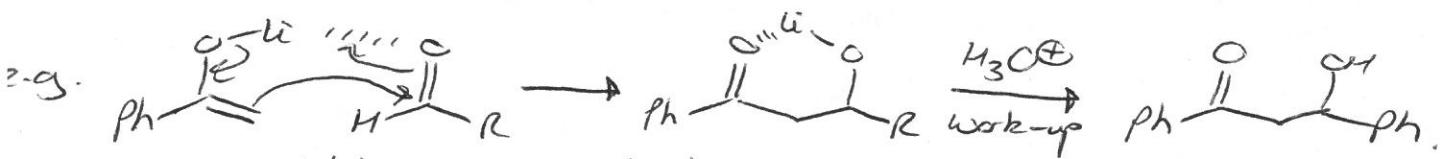

- Lithium endates.

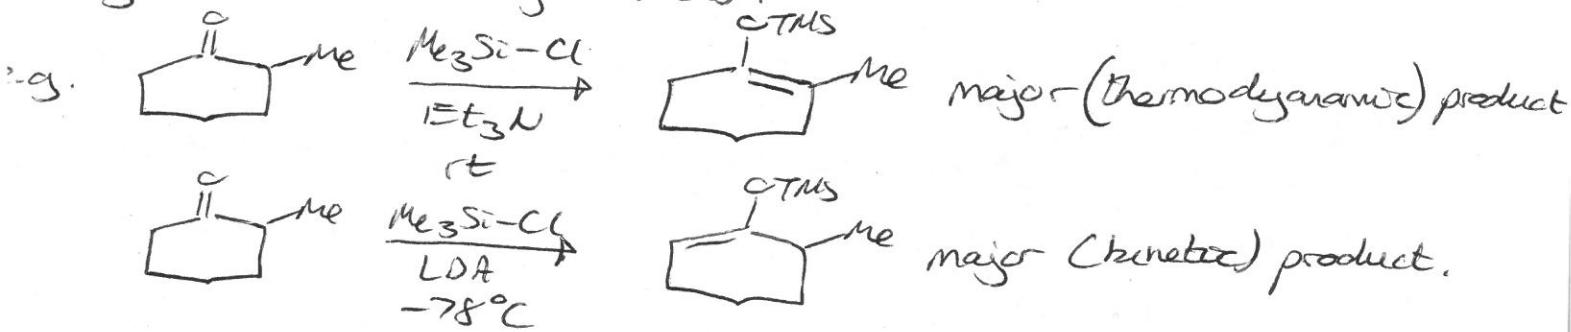

Note: The lithium enolate does not react with the starting ketone at  $-78^\circ\text{C}$  as deprotection at  $-78^\circ\text{C}$  is much faster than the addition reaction. In general, the least hindered hydrogen atom is deprotected fastest (kinetic control).

- Aldol reaction.

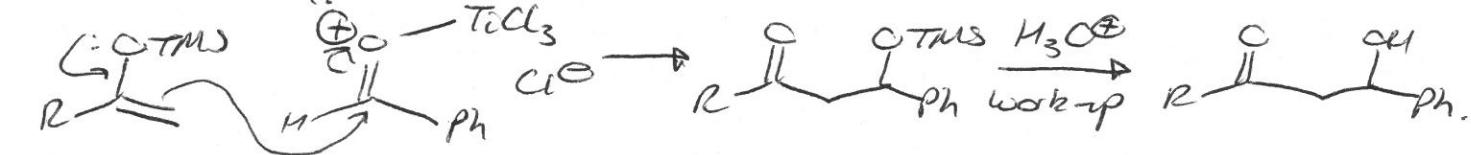

Note: cross-aldo reaction at low T then allow to warm up  $\Rightarrow$  quench using aqueous acid ( $\text{H}_3\text{O}^+$ ).

- Silyl end ethers. (regiocarbonyl)

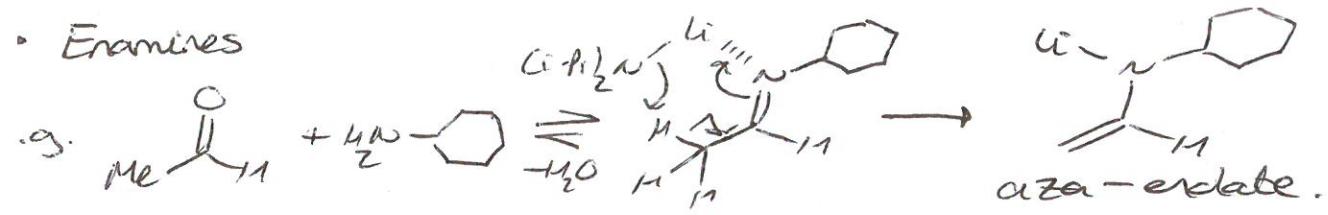

Note: Thermodynamic product  $\Rightarrow$  most stable  $\Rightarrow$  tetrasubstituted olefin.  
Kinetic product  $\Rightarrow$  most accessible hydrogen atom deprotected at low T.

- Aldol reaction.

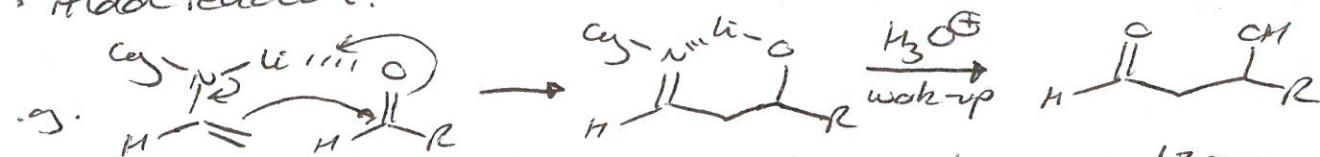

Note: Silyl end ethers only react with aldehydes and ketones using catalytic amounts of a Lewis acid such as  $\text{TiCl}_4$ .

• Enamines

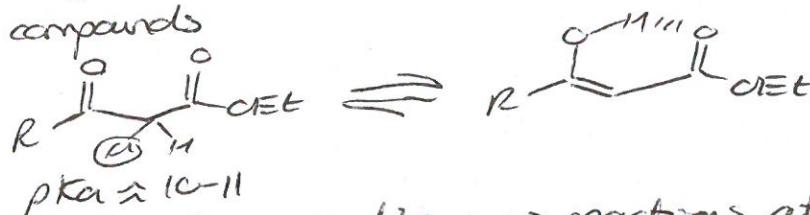

• Aldol reaction.

Note: imine hydrolysed under acidic work-up conditions.

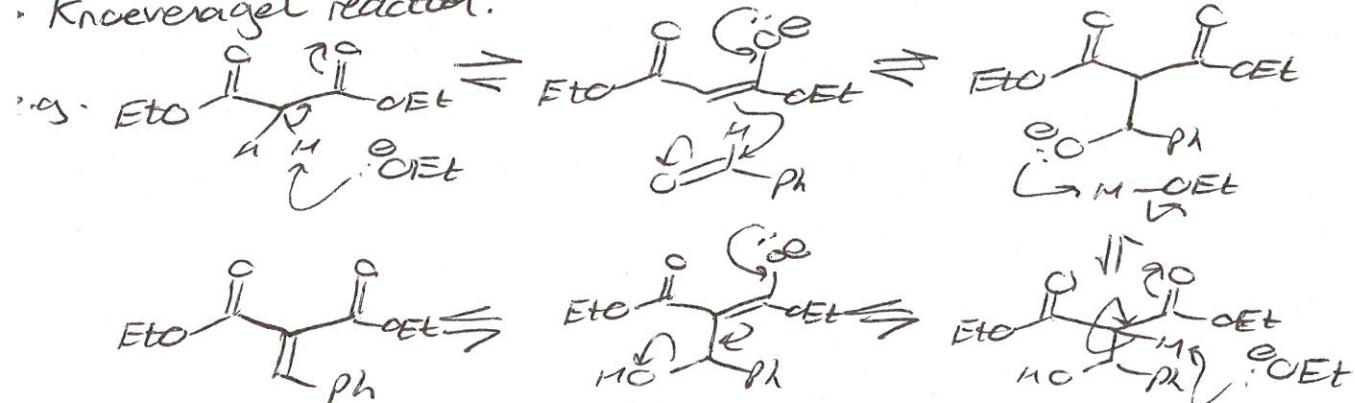

• 1,3-dicarbonyl compounds

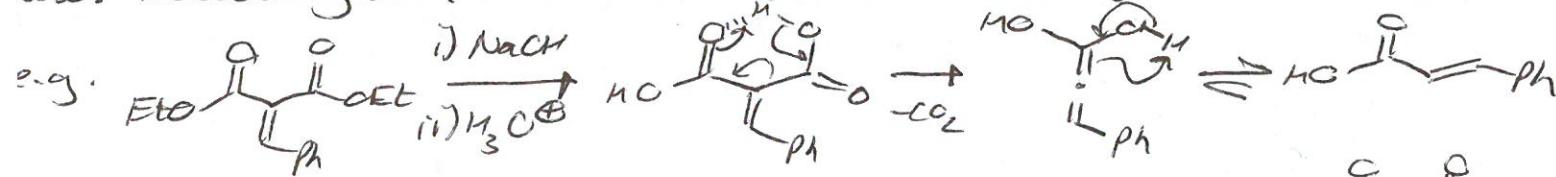

$$pK_a \approx 10-11$$

Note: No need for anhydrous conditions  $\Rightarrow$  reactions at rt or higher. End gem stable due to H-bonding. Simple way to activate carbon atoms adjacent to esters.

• Knoevenagel reaction.

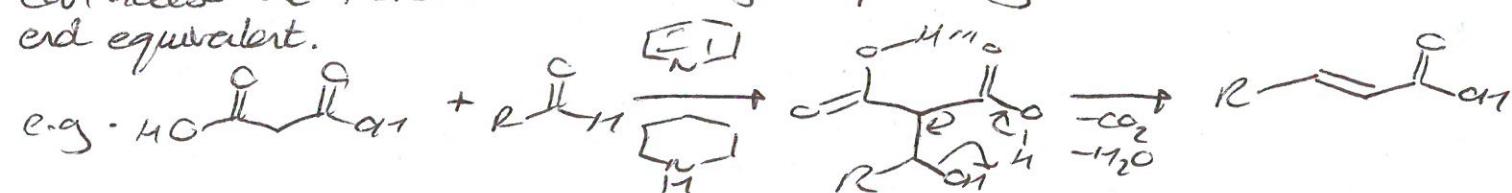

Note: Decarbonylation can be used to remove one of the carbonyl groups.

Note: This procedure can also be used with  $\beta$ -ketoesters e.g.

• Doebner-Moore reaction.

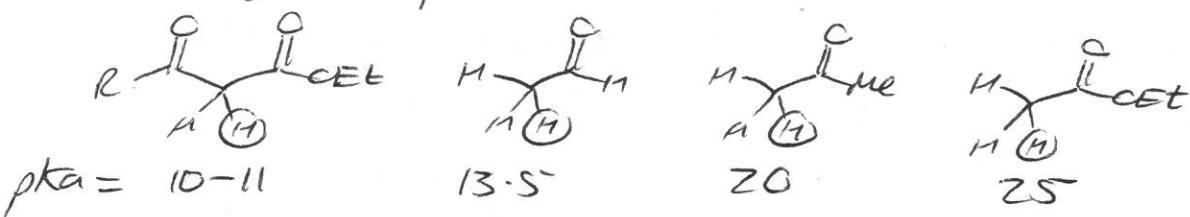

Can access the monocarboxylic acid in a single step using malonic acid as the end equivalent.

Note: Decarbonylation can also take place using  $\beta$ -ketoads e.g.

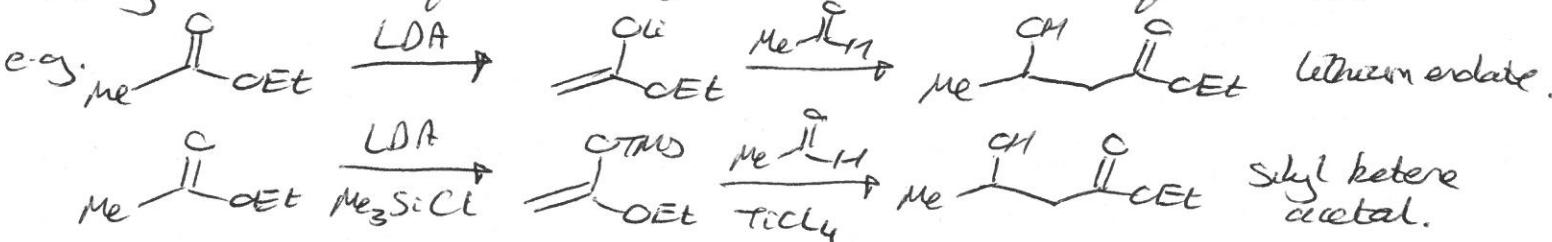

## Lecture 5

- Reading Clayden Ch 25, 26.
- A reminder of some pK<sub>a</sub>s.

Note: The  $\alpha$ -hydrogens in esters are less acidic than others.

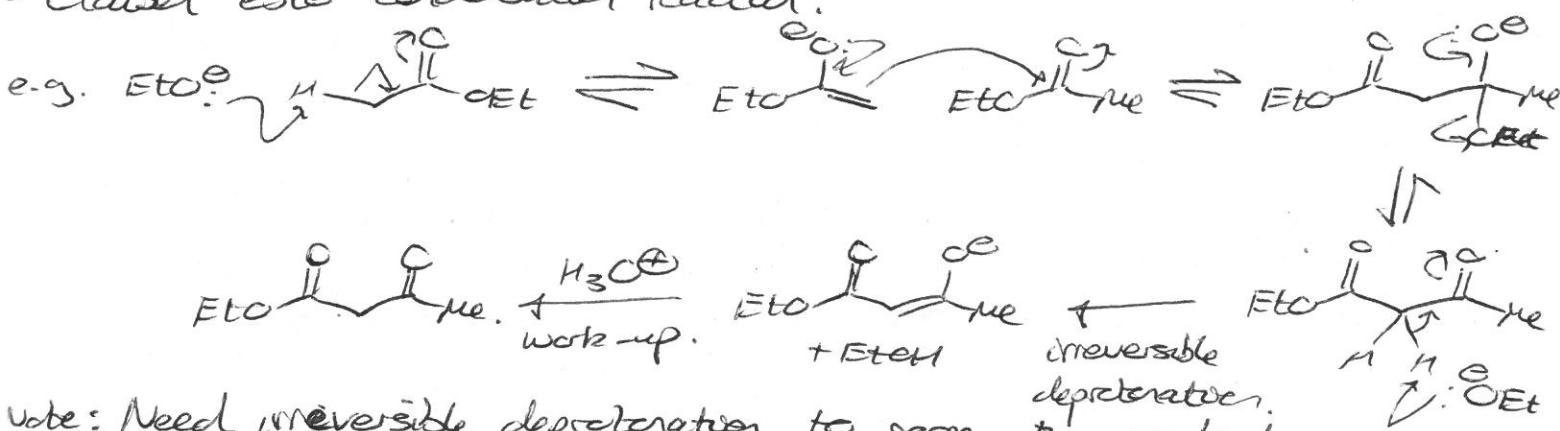

- Strong bases are required to form ester enolate equivalents.

Note: Weaker bases like NaOEt can be used but the solution will exist as a mixture of the ester and the enolate anion.

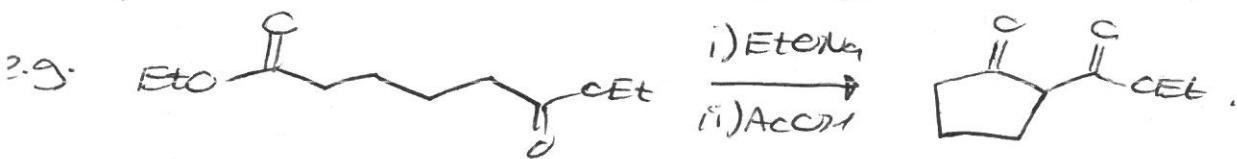

- Claisen ester condensation reaction.

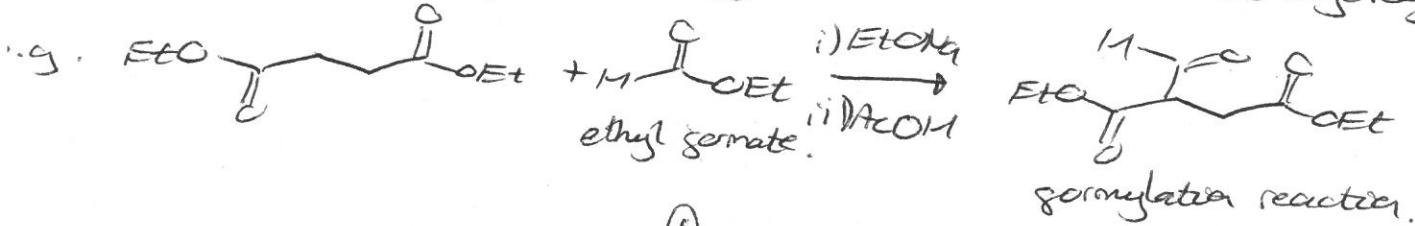

Note: Need irreversible deprotection to form the product  $\Rightarrow$  requires 1 equivalent of base.

- Intramolecular Claisen condensation.

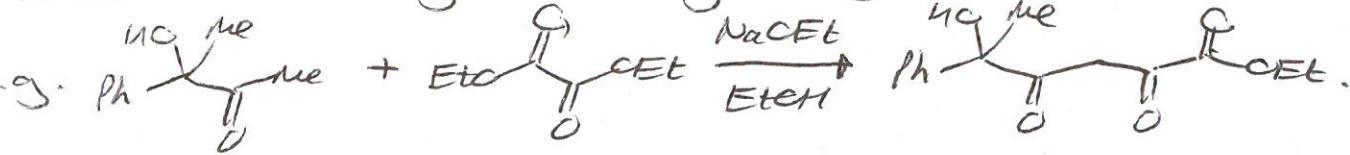

### Cross-Claisen condensations

Either one ester is particularly reactive or has no  $\alpha$ -hydrogens.

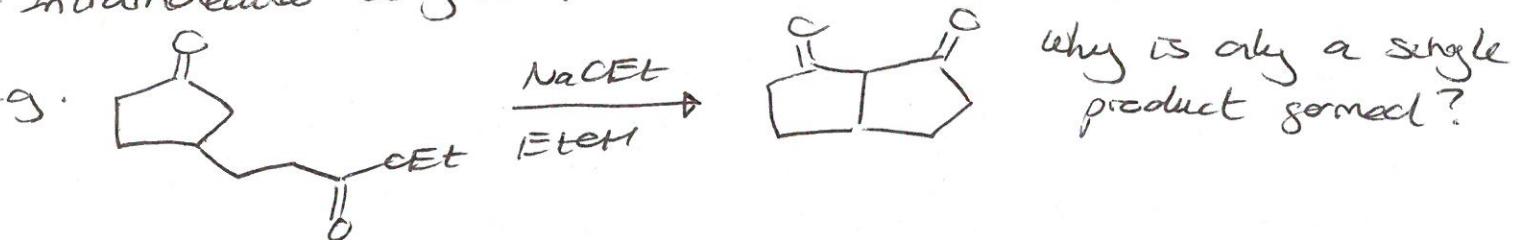

Some related enolate transformations.

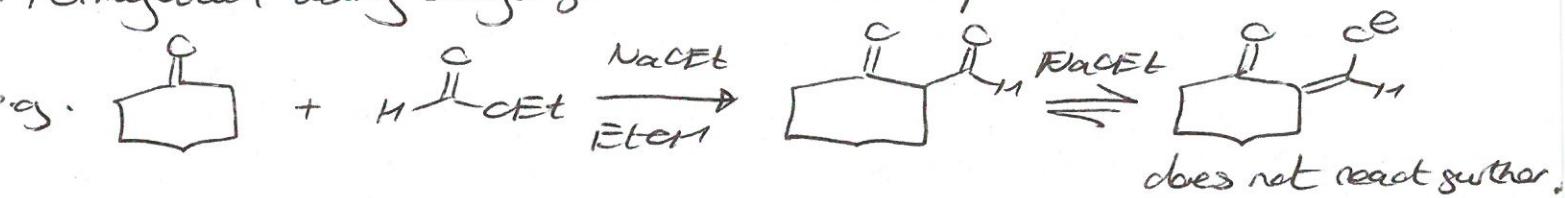

Intermolecular acylation using diethyl oxalate as electrophile.

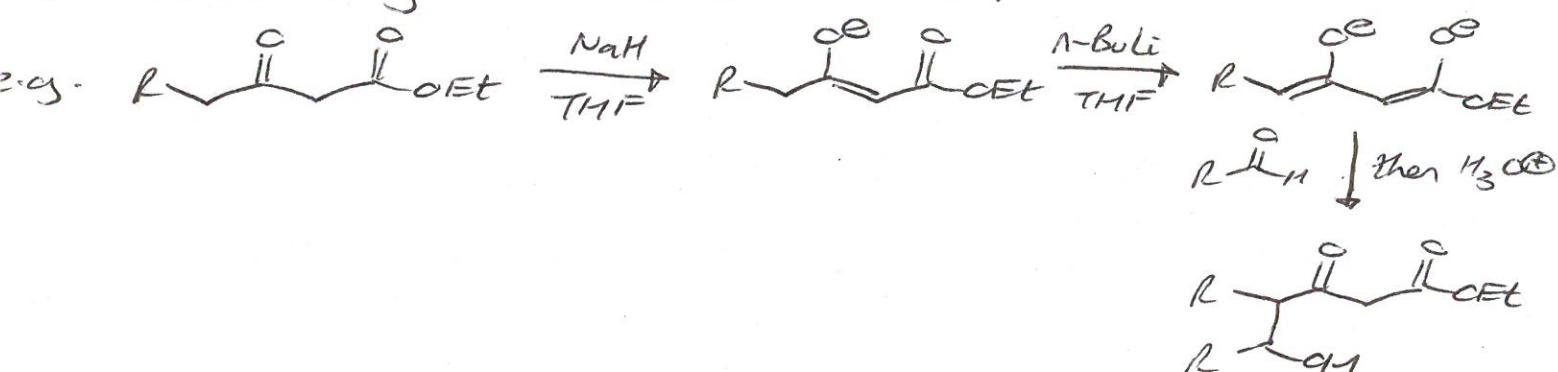

Intramolecular acylation

Formylation using ethyl formate as electrophile.

Dianion chemistry (acetooacetate dianion).

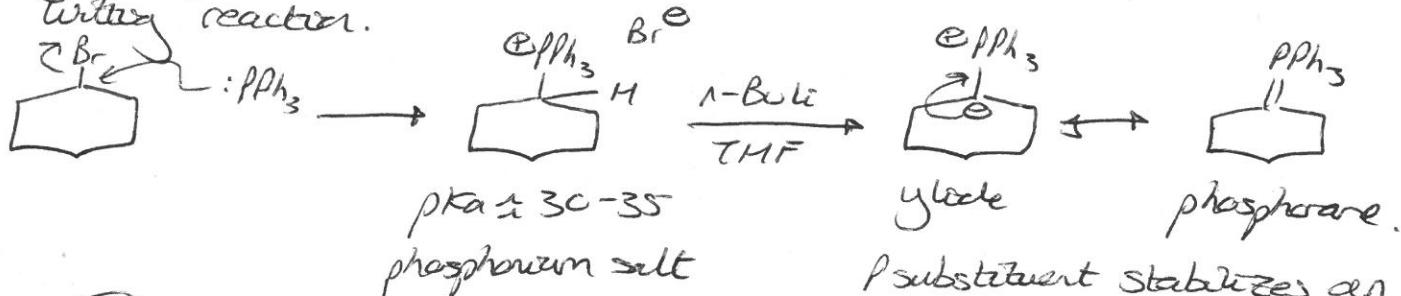

Note: Dianion reacts through less stable anion (kinetic control).  
Can give less stable kinetic product if reactions are irreversible or low T is used.

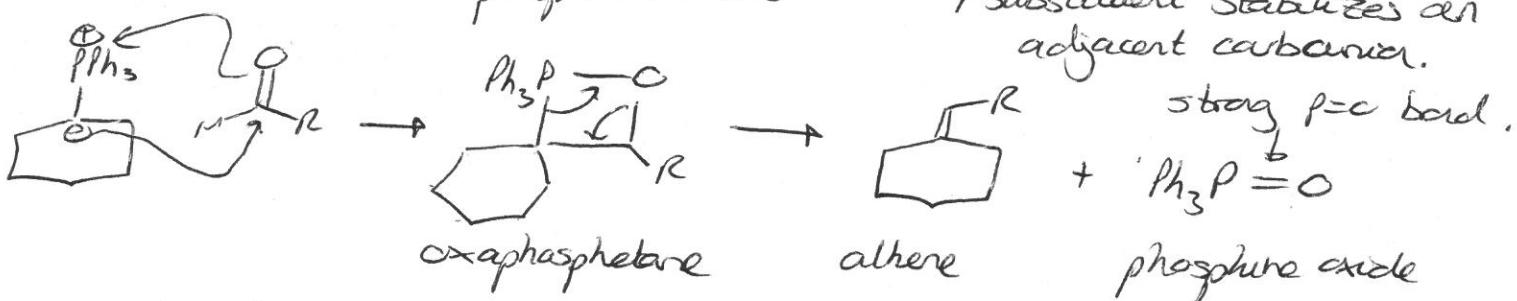

## Lecture 6

- Reading Clayden Ch 27
- The Wittig reaction.

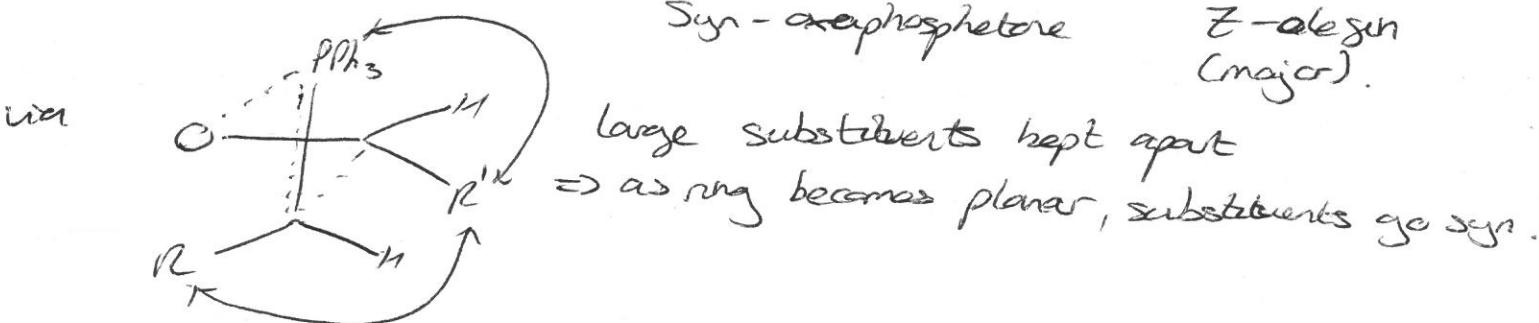

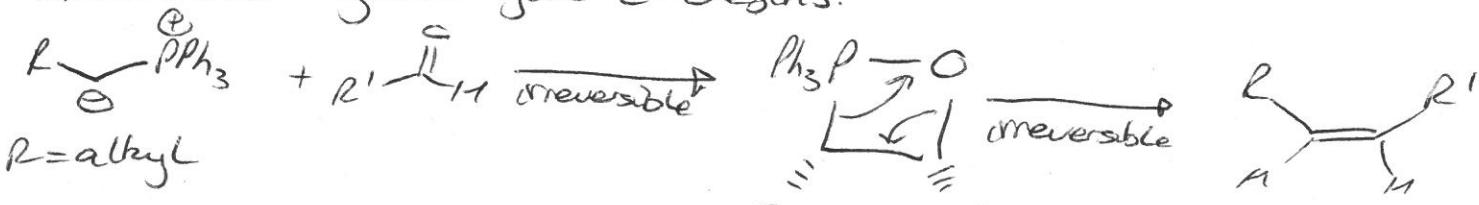

e.g.

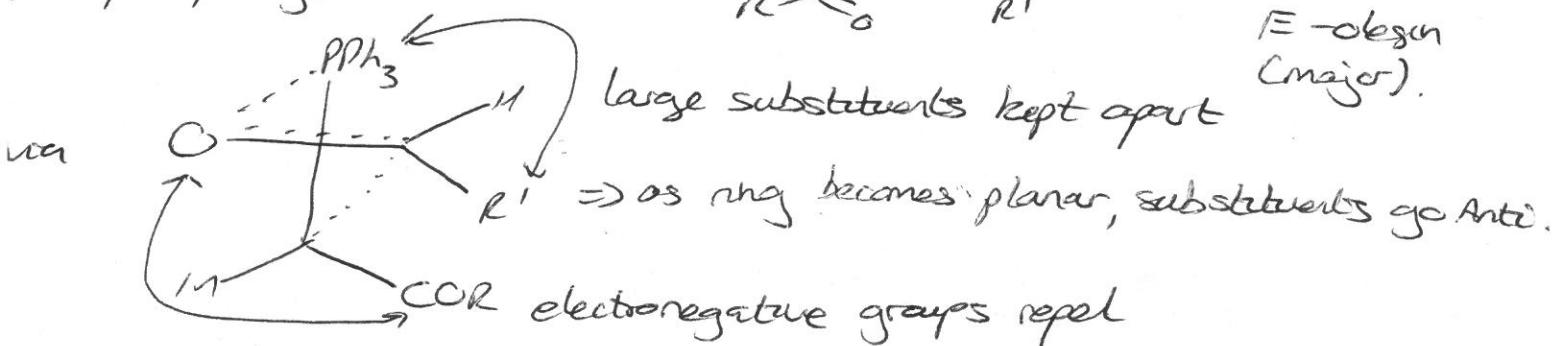

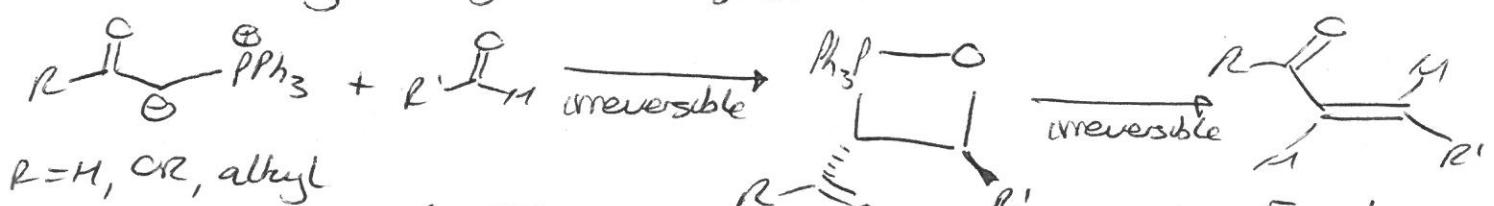

P substituent stabilizes an adjacent carbamion.

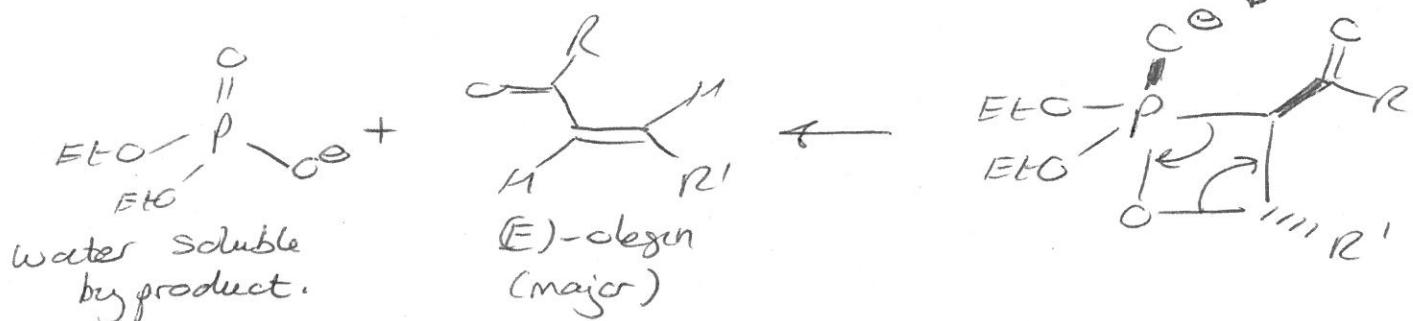

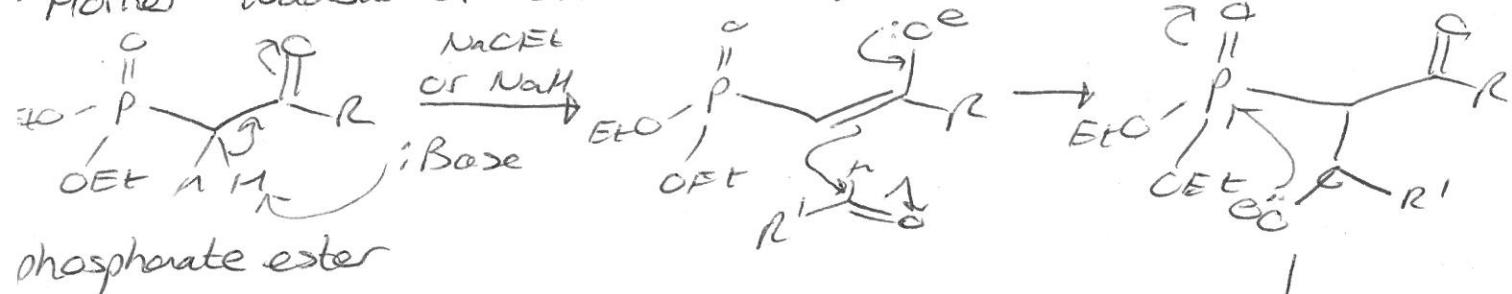

- Unstabilized ylides give Z-olefins.

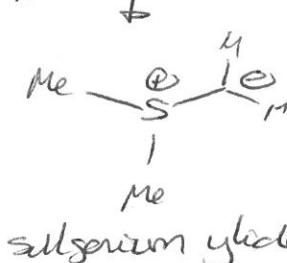

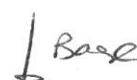

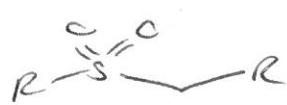

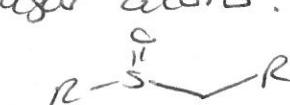

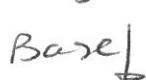

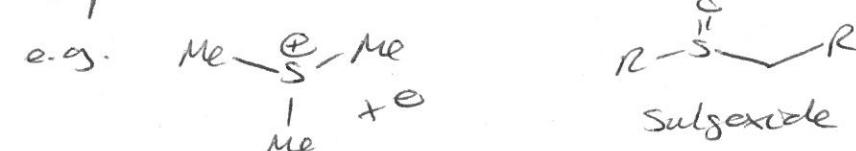

- Stabilized ylides give E-olefins.

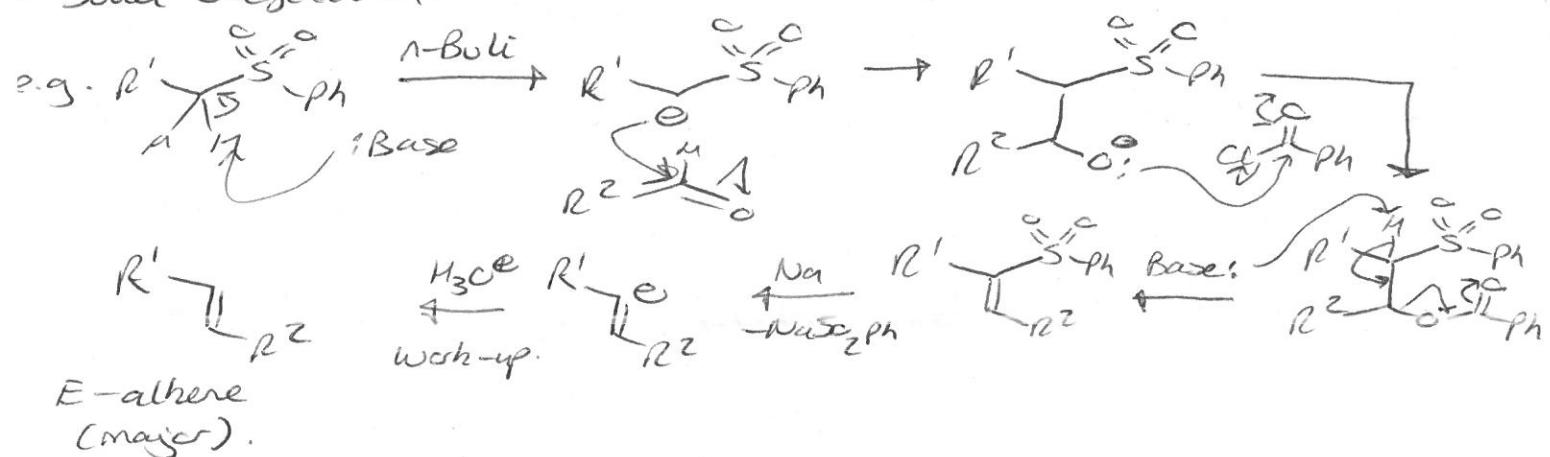

- Horner-Wadsworth-Emmons (HWE) reaction.

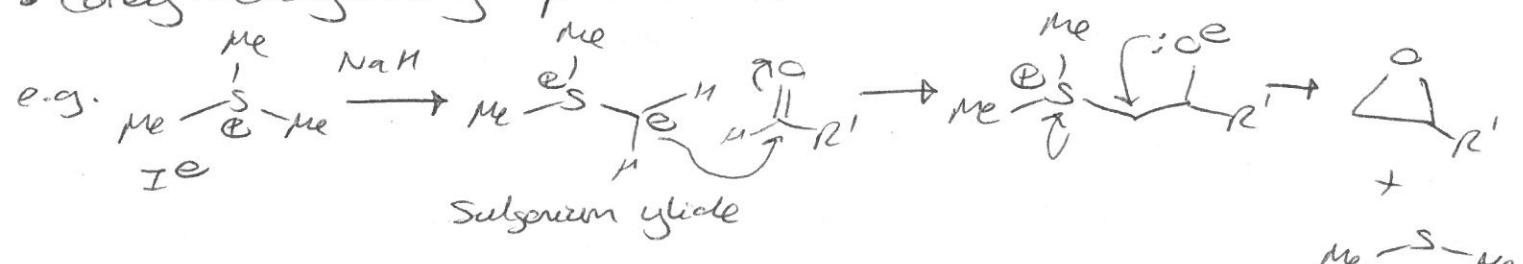

- Deprotection  $\propto$  to sugar atoms.

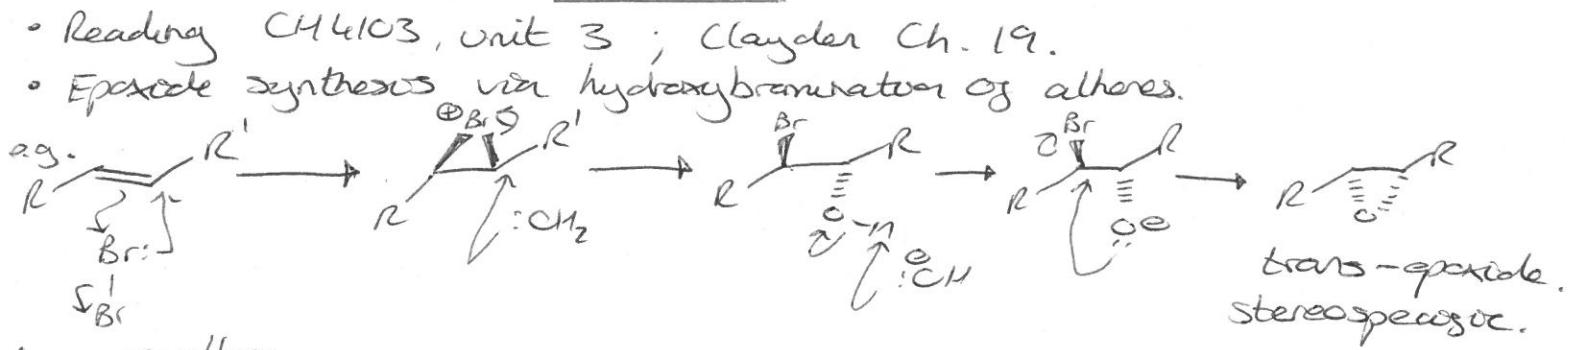

## • Sulic Olegnathus.

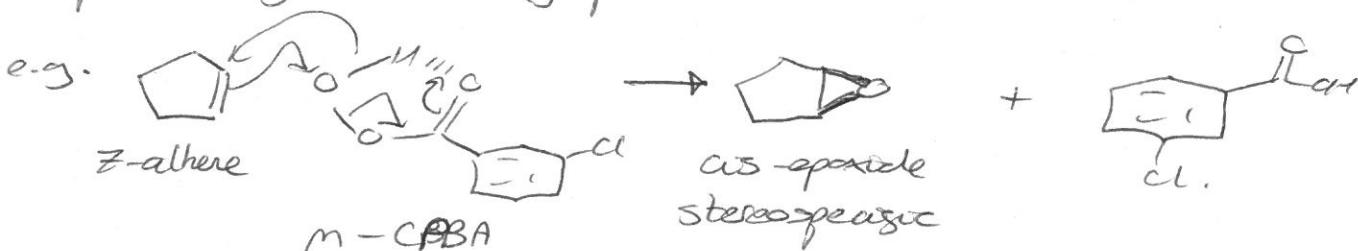

- Corey - Chaykovsky epoxidation.

## Lecture 7

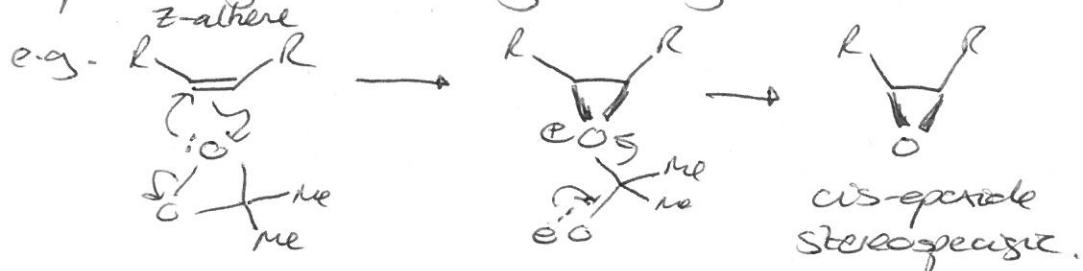

- Epoxide synthesis using peracids.

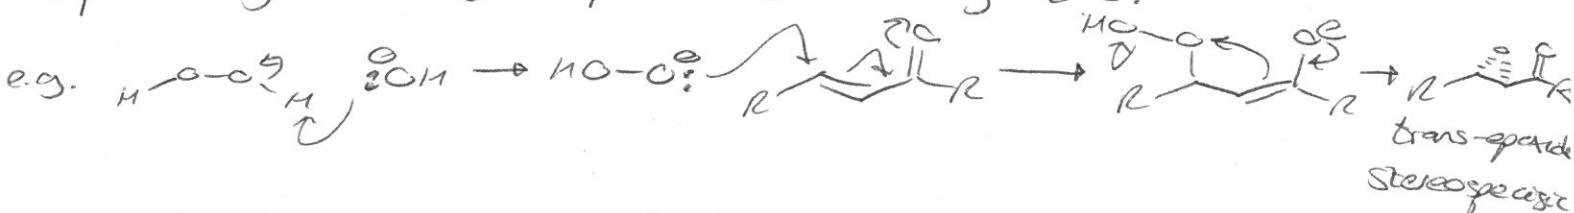

Note: The reaction rate increases as the oxygen becomes more substituted (more nucleophilic).

- Epoxide synthesis using dimethylsioxane (DMSO)

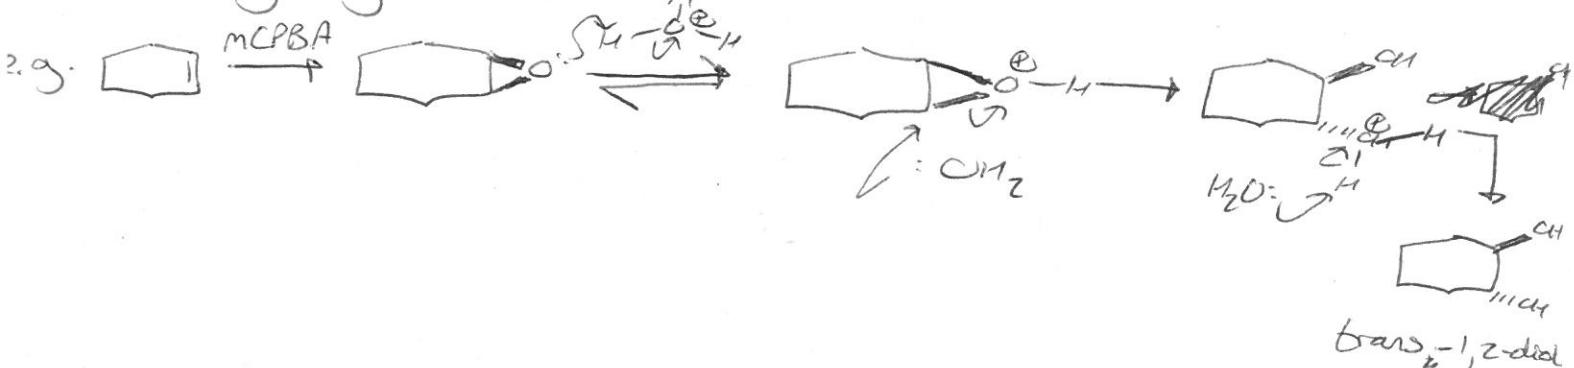

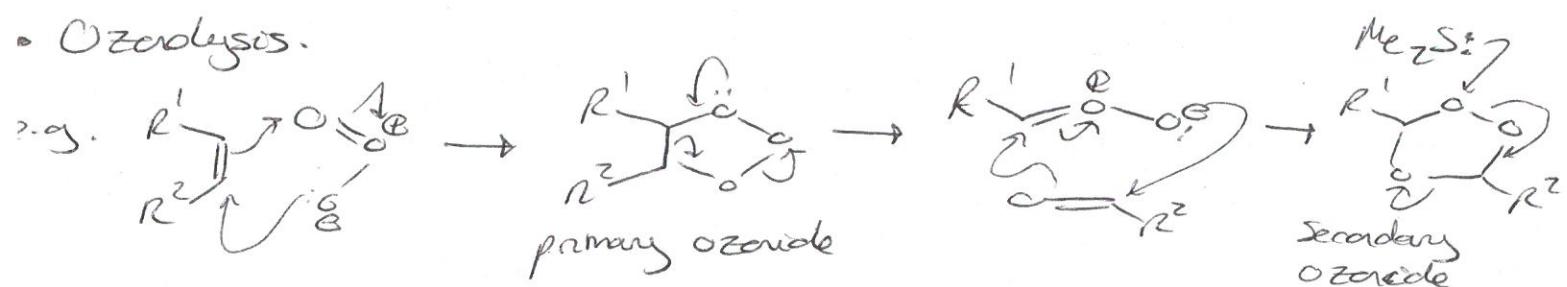

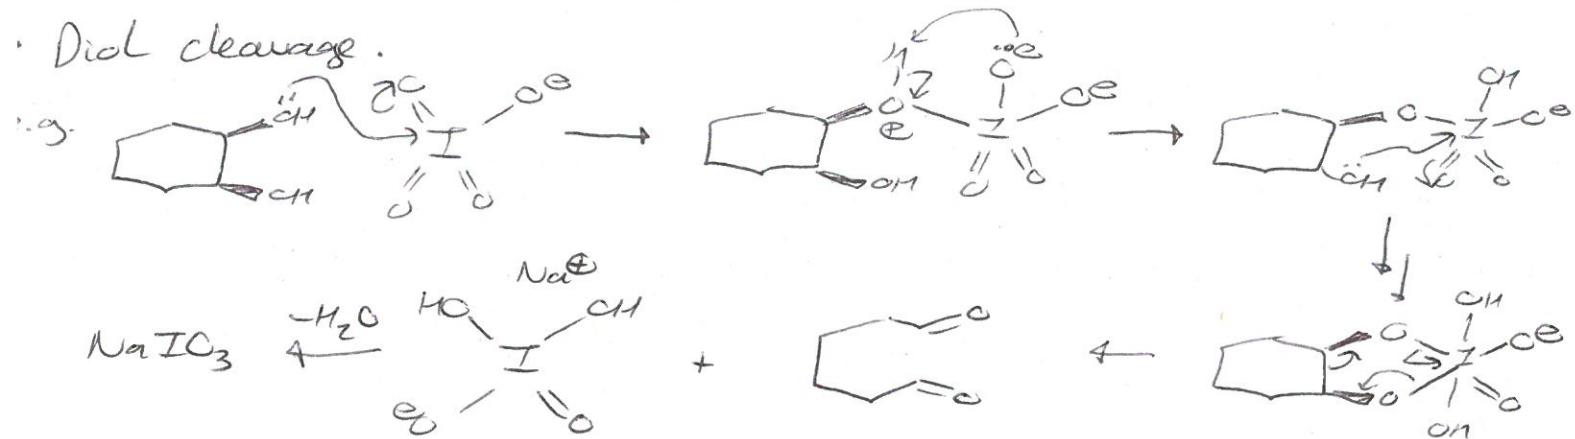

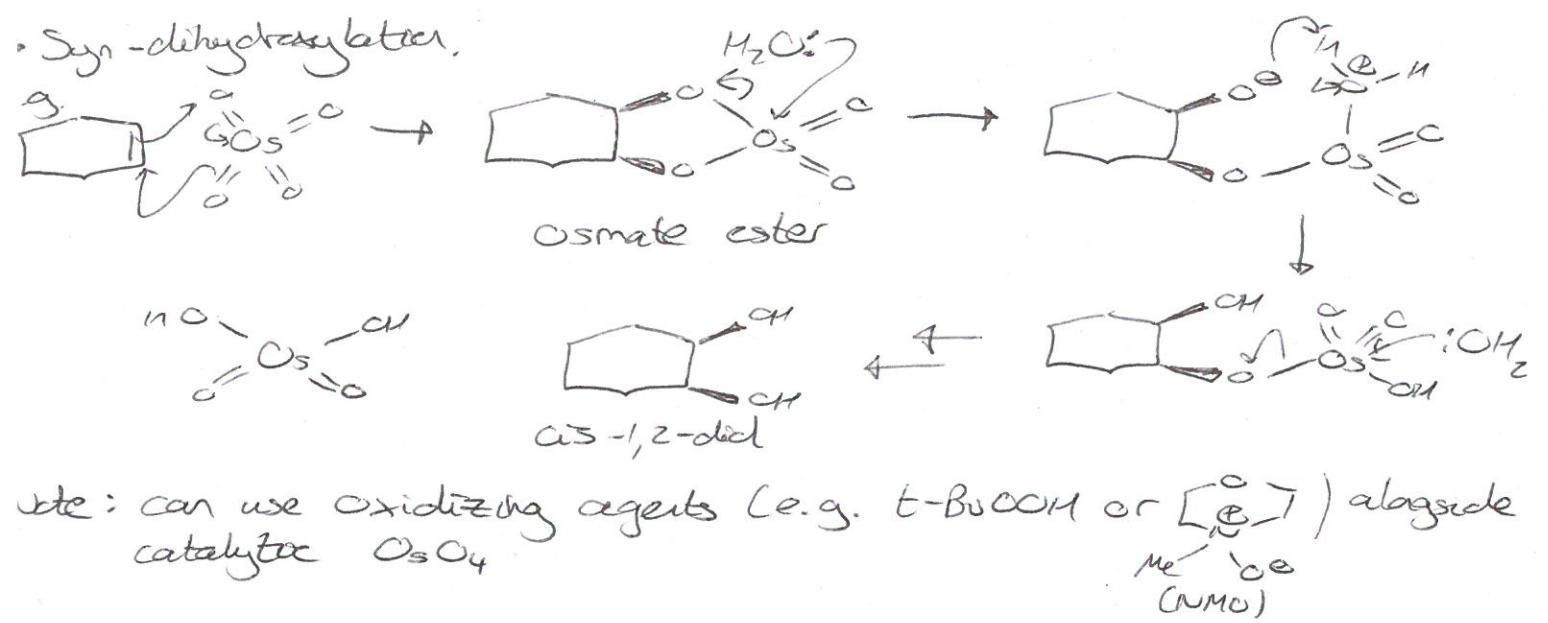

- Epoxide synthesis of  $\text{e}^-$ -poor oxygens using  $\text{H}_2\text{O}_2$ . (See unit 2 references)

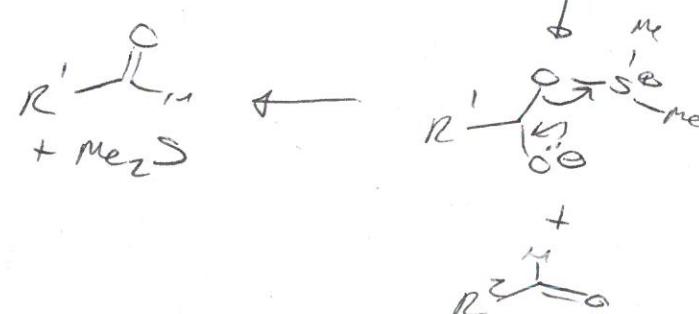

Note:  $\text{pK}_a(\text{H}_2\text{O}_2) = 11.8$     $\text{pK}_a(\text{H}_2\text{O}) = 15.7$  therefore hydroxide can deprotect ~~per~~ hydrogen peroxide.

- Anti-dihydroxylation of alkenes.

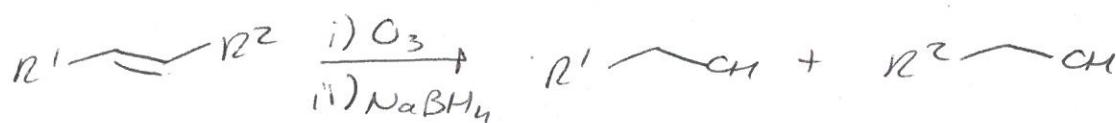

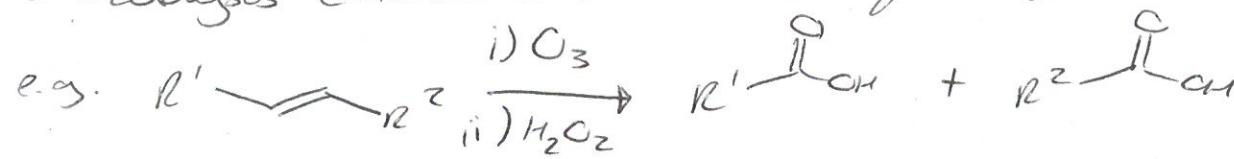

Note: can also use  $\text{PPh}_3$  instead of  $\text{Me}_2\text{S}$ .

• Ozonolysis (oxidative + reductive quenches).

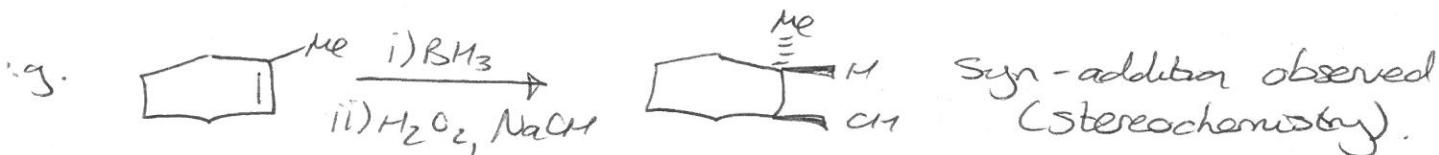

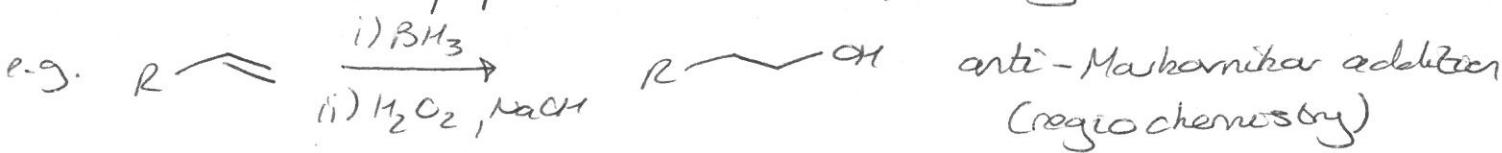

## Lecture 8

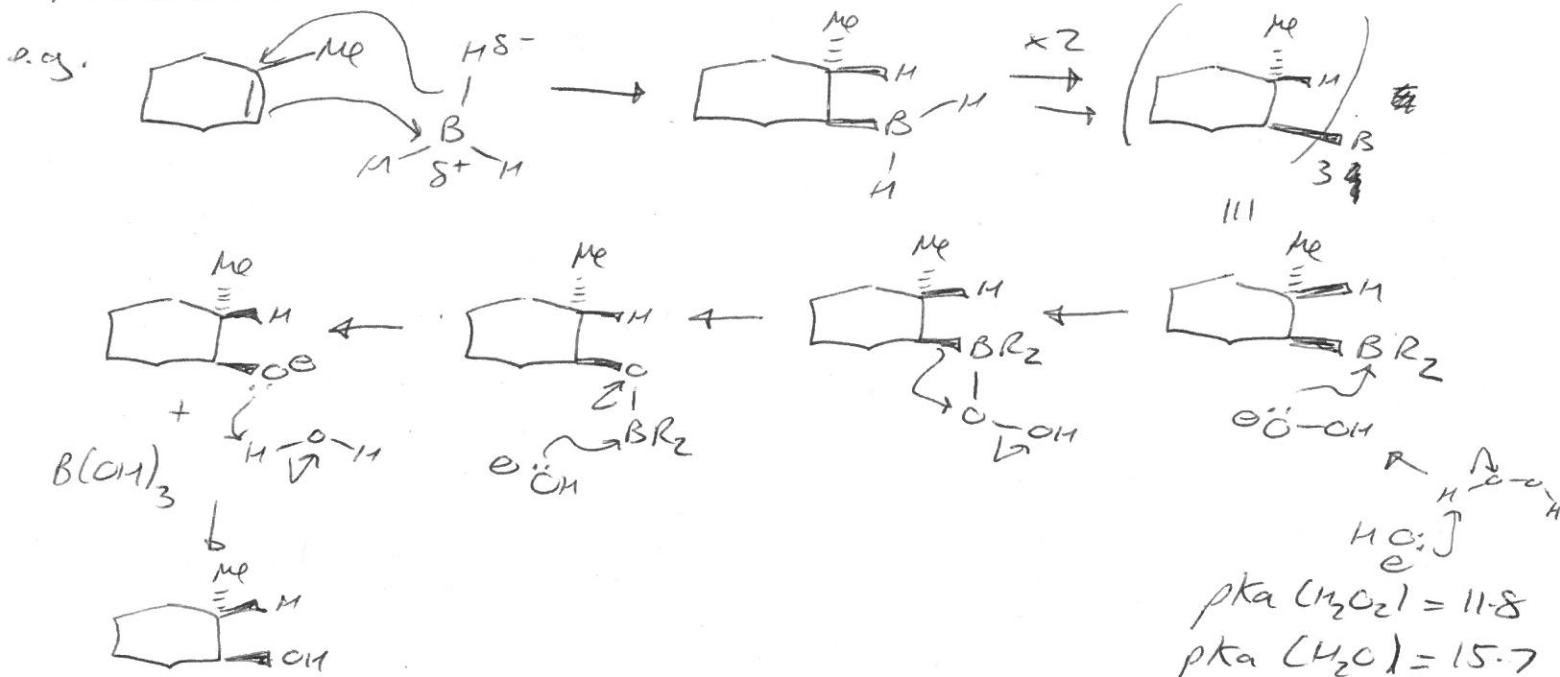

- Reading Clayden Ch. 19.

- Hydroboration / oxidation.

Alcohols can be prepared in two steps using borane chemistry.

- Mechanism.

Note: Boron ( $\text{EN} = 2.0$ ) and Hydrogen ( $\text{EN} = 2.2$ ) polarises B-H bond.

+  $\text{BH}_3$  larger than H.  $\text{BH}_3$  adds to least hindered end. Also,  $\text{C}=\text{C}$   $\pi$  bond adds to B  $2p$  orbital so +ve charge on more substituted carbon atom. The oxidation proceeds with retention of configuration.

- Oxymercuration

Access the opposite regioisomer.

- Mechanism.
